

Does interictal event history feed back into the slow state, or only read it out?

each point is one patient; every block is held-out time the model never saw, and no two blocks overlap

burden = letting an event's occurrence, size and local rate into the state; content = letting what the event looked like in on top, at the same count and instants

A how many events the next block will contain

B what those events look like, given any occurred

grey band = what a rerun of the same model is worth at that horizon; an effect inside it is refit-sized

6 patient point(s) off scale, value printed; open arrow = interval continues past the axis

grey band = what a rerun of the same model is worth at that horizon; an effect inside it is refit-sized

4 patient point(s) off scale, value printed; open arrow = interval continues past the axis

C what one interictal event does to the next block, with a sign

D how much independent held-out time each patient contributes
